In order to measure a person's progress during rehabilitation treatment, it is necessary to use a standard rating scale. The scale most frequently used is the Functional Independence Measurement or FIM. The patient's levels of independence in several areas are measured and that total is part of the outcome measurement. This scale gives professionals an accurate way of communicating patient needs, helps set goals for the treatment plan, and helps measure the gains made by the patient. It also helps the rehabilitation unit measure its success with all patients treated. This report card is to communicate the outcomes produced here at this hospital.

What are UDSMR and FIM?

The Uniform Data System for Medical Rehabilitation (UDSMR) is a national databank that provides a way to document the severity of a patient's disability and the results of medical rehabilitation in a consistent manner. Through the use of the Functional Independence Measure (FIM), clinicians are able to follow changes in the functional status of patients from the start of rehabilitative care through discharge and follow-up. The FIM tool is a numeric rating of the patient's level of independence in 18 areas. The scale ranges from total independence (7) to total dependence (1). This data is compared with that of regional and national rehabilitation facilities and provides information used in determining the effectiveness and efficiency of care, evaluation of program outcomes, and assists in the clinical management of the patient.
